CS124 Lecture 22

An introductory example

Suppose that a company that produces three products wishes to decide the level of production of each so as to maximize profits. Let x_1 be the amount of Product 1 produced in a month, x_2 that of Product 2, and x_3 that of Product 3. Each unit of Product 1 yields a profit of 100, each unit of Product 2 a profit of 600, and each unit of Product 3 a profit of 1400. There are limitations on x_1 , x_2 , and x_3 (besides the obvious one, that x_1 , x_2 , $x_3 \ge 0$). First, x_1 cannot be more than 200, and x_2 cannot be more than 300, presumably because of supply limitations. Also, the sum of the three must be, because of labor constraints, at most 400. Finally, it turns out that Products 2 and 3 use the same piece of equipment, with Product 3 using three times as much, and hence we have another constraint $x_2 + 3x_3 \le 600$. What are the best levels of production?

We represent the situation by a *linear program*, as follows:

The set of all *feasible* solutions of this linear program (that is, all vectors in 3-d space that satisfy all constraints) is precisely the polyhedron shown in Figure 22.1.

We wish to maximize the linear function $100x_1 + 600x_2 + 1400x_3$ over all points of this polyhedron. Geometrically, the linear equation $100x_1 + 600x_2 + 1400x_3 = c$ can be represented by a plane parallel to the one determined by the equation $100x_1 + 600x_2 + 1400x_3 = 0$. This means that we want to find the plane of this type that touches the polyhedron and is as far towards the positive orthant as possible. Obviously, the optimum solution will be a vertex (or the optimum solution will not be unique, but a vertex will do). Of course, two other possibilities with linear programming are that (a) the optimum solution may be infinity, or (b) that there may be no feasible solution at all.

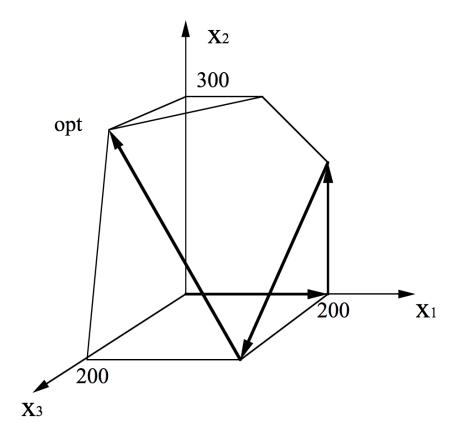

Figure 22.1: The feasible region

For this problem, an optimal solution exists, and moreover we shall show that it is easy to find.

Linear programs

Linear programs, in general, have the following form: there is an *objective function* that one seeks to optimize, along with *constraints* on the variables. The objective function and the constraints are all *linear* in the variables; that is, all equations have no powers of the variables, nor are the variables multiplied together. As we shall see, many problems can be represented by linear programs, and for many problems it is an extremely convenient representation. So once we explain how to solve linear programs, the question then becomes how to reduce other problems to linear programming (LP).

There are polynomial time algorithms for solving linear programs. In practice, however, such problems are solved by the *simplex method* devised by George Dantzig in 1947. The simplex method starts from a vertex (in this case the vertex (0,0,0)) and repeatedly looks for a vertex that is adjacent, and has better objective value. That is, it is a kind of *hill-climbing* in the vertices of the polytope. When a vertex is found that has no better neighbor, simplex

stops and declares this vertex to be the optimum. For example, in the figure one of the possible paths followed by simplex is shown. No known variant of the simplex algorithm has been proven to take polynomial time, and most of the variations used in practice have been shown to take exponential time on some examples. Fortunately, in practice, bad cases rarely arise, and the simplex algorithm runs extremely quickly. There are now implementations of simplex that solve routinely linear programs with *many thousands* of variables and constraints.

Of course, given a linear program, it is possible either that (a) the optimum solution may be infinity, or (b) that there may be no feasible solution at all. If this is the case, the simplex algorithm will discover it.

Reductions between versions of simplex

A general linear programming problem may involve constraints that are equalities or inequalities in either direction. Its variables may be nonnegative, or could be unrestricted in sign. And we may be either minimizing or maximizing a linear function. It turns out that we can easily translate any such version to any other. One such translation that is particularly useful is from the general form to the one required by simplex: *minimization*, *nonnegative variables*, *and equality constraints*.

To turn an inequality $\sum a_i x_i \le b$ into an equality constraint, we introduce a new variable s (the *slack variable* for this inequality), and rewrite this inequality as $\sum a_i x_i + s = b, s \ge 0$. Similarly, any inequality $\sum a_i x_i \ge b$ is rewritten as $\sum a_i x_i - s = b, s \ge 0$; s is now called a *surplus* variable.

We handle an unrestricted variable x as follows: we introduce two nonnegative variables, x^+ and x^- , and replace x by $x^+ - x^-$ everywhere. The idea is that we let $x = x^+ - x^-$, where we may restrict both x^+ and x^- to be nonnegative. This way, x can take on any value, but there are only nonnegative variables.

Finally, to turn a maximization problem into a minimization one, we just multiply the objective function by -1.

A production scheduling example

We have the demand estimates for our product for all months of 1997, d_i : i = 1,...,12, and they are very uneven, ranging from 440 to 920. We currently have 30 employees, each of which produce 20 units of the product each month at a salary of 2,000; we have no stock of the product. How can we handle such fluctuations in demand? Three ways:

• overtime —but this is expensive since it costs 80% more than regular production, and has limitations, as workers can only work 30% overtime.

- hire and fire workers —but hiring costs 320, and firing costs 400.
- store the surplus production —but this costs 8 per item per month

This rather involved problem can be formulated and solved as a linear program. As in all such reductions, the crucial first step is defining the variables:

- Let w_0 be the number of workers we have the *i*th month —we have $w_0 = 30$.
- Let x_i be the production for month i.
- o_i is the number of items produced by overtime in month i.
- h_i and f_i are the number of workers hired/fired in the beginning of month i.
- s_i is the amount of product stored after the end of month i.

We now must write the constraints:

- $x_i = 20w_i + o_i$ —the amount produced is the one produced by regular production, plus overtime.
- $w_i = w_{i-1} + h_i f_i, w_i \ge 0$ —the changing number of workers.
- $s_i = s_{i-1} + x_i d_i \ge 0$ —the amount stored in the end of this month is what we started with, plus the production, minus the demand.
- $o_i \le 6w_i$ —only 30% overtime.

Finally, what is the objective function? It is

$$\min 2000 \sum w_i + 400 \sum f_i + 320 \sum h_i + 8 \sum s_i + 180 \sum o_i,$$

where the summations are from i = 1 to 12.

A Communication Network Problem

We have a network whose lines have the bandwidth shown in Figure 22.2. We wish to establish three calls: one between A and B (call 1), one between B and C (call 2), and one between A and C (call 3). We must give each call at least 2 units of bandwidth, but possibly more. The link from A to B pays 3 per unit of bandwidth, from B to C

pays 2, and from A to C pays 4. Notice that each call can be routed in two ways (the long and the short path), or by a combination (for example, two units of bandwidth via the short route, and three via the long route). Suppose we are a shady network administrator, and our goals is to maximize the network's income (rather than minimize the overall cost). How do we route these calls to maximize the network's income?

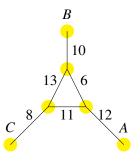

Figure 22.2: A communication network

This is also a linear program. We have variables for each call and each path (long or short); for example x_1 is the short path for call 1, and x'_2 the long path for call 2. We demand that (1) no edge bandwidth is exceeded, and (2) each call gets a bandwidth of 2.

$$\max 3x_1 + 3x'_1 + 2x_2 + 2x'_2 + 4x_3 + 4x'_3$$

$$x_1 + x'_1 + x_2 + x'_2 \leq 10$$

$$x_1 + x'_1 + x_3 + x'_3 \leq 12$$

$$x_2 + x'_2 + x_3 + x'_3 \leq 8$$

$$x_1 + x'_2 + x'_3 \leq 6$$

$$x'_1 + x_2 + x'_3 \leq 13$$

$$x'_1 + x'_2 + x_3 \leq 11$$

$$x_1 + x'_1 \geq 2$$

$$x_2 + x'_2 \geq 2$$

$$x_2 + x'_2 \geq 2$$

$$x_3 + x'_3 \geq 2$$

$$x_1, x'_1, \dots, x'_3 \geq 0$$

The solution, obtained via simplex in a few milliseconds, is the following: $x_1 = 0, x'_1 = 7, x_2 = x'_2 = 1.5, x_3 = 0.5, x'_3 = 4.5.$

Question: Suppose that we removed the constraints stating that each call should receive at least two units. Would the optimum change?

Approximate Separation

An interesting last application: Suppose that we have two sets of points in the plane, the *black points* (x_i, y_i) : i = 1, ..., m and the *white points* (x_i, y_i) : i = m+1, ..., m+n. We wish to separate them by a straight line ax+by=c, so that for all black points $ax+by \le c$, and for all white points $ax+by \ge c$. In general, this would be impossible. Still, we may want to separate them by a line that minimizes the sum of the "displacement errors" (distance from the boundary) over all misclassified points. Here is the LP that achieves this:

$$\begin{array}{ll} \min e_1 & +e_2 + \ldots + e_m + e_{m+1} + \ldots + e_{m+n} \\ e_1 \geq & ax_1 + by_1 - c \\ e_2 \geq & ax_2 + by_2 - c \\ \vdots \\ e_m \geq & ax_m + by_m - c \\ e_{m+1} \geq & c - ax_{m+1} - by_{m+1} \\ \vdots \\ e_{m+n} \geq & c - ax_{m+n} - by_{m+n} \\ e_i \geq 0 \end{array}$$
